(Dated: 02 November, 2004)

We study fidelity decay by a uniform semiclassical approach, in the three perturbation regimes, namely, the perturbative regime, the Fermi-golden-rule (FGR) regime, and the Lyapunov regime. A semiclassical expression is derived for fidelity of initial Gaussian wave packets with width of the order $\sqrt{\hbar}$ ($\hbar$ being the effective Planck constant). Short time decay of fidelity of initial Gaussian wave packets is also studied, with respect to two time scales introduced in the semiclassical approach. In the perturbative regime, it is confirmed numerically that fidelity has the FGR decay before the Gaussian decay sets in. An explanation is suggested to a non-FGR decay in the FGR regime, which has been observed in a system with weak chaos in the classical limit, by using the Levy distribution as an approximation for the distribution of action difference. In the Lyapunov regime, it is shown that the average of the logarithm of fidelity may have roughly the Lyapunov decay within some time interval, in systems possessing large fluctuation of the finite-time Lyapunov exponent in the classical limit.

I. INTRODUCTION

It is well known that, in classically chaotic systems, time evolution of trajectories in phase space is sensitive to small changes in initial conditions, as well as in parameters in the Hamiltonians. On the other hand, time evolution of state-vectors in Hilbert space is insensitive to small change of initial conditions. Nearly twenty years ago, Peres observed that small change in perturbation parameters can be employed in the study of the stability of quantum motion in the Hilbert space [1], supported by further numerical investigations [2, 3]. The quantity used to measure the stability of quantum motion is the quantum Loschmidt echo, or fidelity in the field of quantum information [4, 5]. It is an overlap of the evolution of the same initial state under two Hamiltonians with slight difference in the classical limit, $M(t) = |m(t)|^2$, where

$$m(t) = \langle \Psi_0 | \exp(iH_1 t/\hbar) \exp(-iH_0 t/\hbar) | \Psi_0 \rangle. \quad (1)$$

Here H_0 is the Hamiltonian of a classically chaotic system and $H_1 = H_0 + \epsilon V$ with ϵ being a small quantity.

Fidelity decay has attracted increasing attention, since the work of Jalabert and Pastawski [6], which relates the decay rate of fidelity to the (maximum) Lyapunov exponent of the underlying classical dynamics. In order to understand the behavior of fidelity in various systems, extensive investigations have been carried out [7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30]. Previous investigations show the existence of at least four regimes of perturbation strength for fidelity decay [7, 8]: (i) In the perturbative regime below a perturbative border, fidelity has a Gaussian decay. In this regime, the typical transition matrix element is smaller than the mean level spacing. (ii) Above the perturbative regime is the Fermi-golden-rule (FGR) regime, with an exponential decay of the fidelity, $M(t) \propto \exp(-\Gamma t)$, where Γ is the half-width of the local

spectral density of states (LDOS) [9]. The decay rate can also be calculated semiclassically [10]. (iii) With increasing perturbation strength, one enters into the Lyapunov regime, in which $M(t) \propto \exp(-\lambda t)$, with λ being the Lyapunov exponent of the underlying classical dynamics [6]. (iv) In the regime above the Lyapunov regime, perturbation strength is so large that the classical perturbation theory fails. Presently, little is known about the decaying behavior of fidelity in this regime. Within a random matrix theory approach, in which fidelity is expressed as the Fourier transform of LDOS, a Gaussian decay was suggested for fidelity decay in this regime [7], without further numerical confirmation (cf. [31, 32] for shape of LDOS in this regime). It is also known that, for time t short enough, fidelity has a quadratic decay, which may be extended to a Gaussian decay, just as a direct result of perturbation theory [21].

Most recent investigations show that the above picture of fidelity decay is incomplete, at least in four aspects. Firstly, in the perturbative regime, numerical results [22] show that fidelity in the kicked rotator model has an exponential decay, which can be described by their semiclassical approximation, before the Gaussian decay sets in at about the Heisenberg time. A random matrix approach to fidelity also suggests an approximately exponential decay of fidelity at t short enough [29]. It is not quite clear whether this exponential decay is the FGR decay or not.

Secondly, a non-FGR decay of fidelity in the expected FGR regime has been found in a system with weak chaos in the classical limit, which is induced by deviation of the distribution of action difference from the expected Gaussian distribution [28]. An analytical description for the rate of the non-FGR decay is still lacking.

Thirdly, in the Lyapunov regime, the decay rate of average fidelity has been found different from the Lyapunov exponent, although still perturbation-independent, in systems possessing large fluctuation in the finite-time

Lyapunov exponent [33, 34], as in the kicked top and kicked rotator models [9, 19, 20]. A semiclassical WKB description of wave packets suggests an $\exp(-\lambda_1 t)$ decay for the fidelity, with $\lambda_1 < \lambda$ [20]. More recently, more general semiclassical expressions of fidelity decay have been derived, with the Lyapunov decay and the λ_1 decay being two limiting cases [30], along the lines of the semiclassical treatment to fidelity in Refs. [6, 8, 10, 22, 28]. However, the situation has not been clarified completely, since numerical results in the kicked top model show that the Lyapunov decay can be resumed in an approximate way, if average is performed on the logarithm of fidelity, but not on the fidelity itself [19].

Finally, in the deep Lyapunov regime, fidelity of initial Gaussian wave packets may have a decay which is super-exponential and much faster than the Lyapunov decay at short initial times [20]. Meanwhile, a decay with a rate of twice the Lyapunov exponent may appear before a time scale introduced in [30], in systems with constant local Lyapunov exponents. A quantitative description of the former decay is still not available and the time scale that separates the two faster than Lyapunov decays is unknown.

In this paper, we use the uniform semiclassical approach introduced in [22] to study the problems mentioned above. This approach is not only a suitable method for numerical evaluation of fidelity, but also a good starting point for analytical study [28, 30]. For simplicity, we study 1D kicked systems only in this paper.

The paper is organized as the following. In Sect. II, we introduce two models, the kicked rotator and the sawtooth map, that will be employed for numerical check of our analytical results. A major difference between the two models is that the sawtooth map has a constant finite-time Lyapunov exponent, while the kicked rotator has large fluctuation in the finite-time Lyapunov exponent. For the sawtooth map, the semiclassical prediction of the rate of FGR-decay can be calculated accurately at some parameter values, meanwhile, it has weak chaos with a structure of cantori in some parameter regime [35].

The validity of the uniform semiclassical approach has been checked numerically for initial point sources [22, 28]. For initial Gaussian wave packets, narrowness of the packets are assumed in deriving the semiclassical expressions of fidelity in [6, 22]. In Sect. III, we show that the expression in [22] fails in describing the fidelity decay, when the width of the initial Gaussian wave packet is of the order $\sqrt{\hbar}$, where $\hbar$ is the effective Planck constant in the 1D kicked systems studied here. By considering the second order term in the Taylor expansion of the action, we derive a modified expression, which works well for this kind of initial wave packets.

In Sect. IV, we discuss short time behavior of fidelity. In particular, a time scale is introduced for fidelity decay of initial Gaussian wave packets, which separates the two faster than Lyapunov decays mentioned above, and an analytical expression is derived for fidelity before this

time scale. Dependence of the first-kick decay of fidelity of initial point sources on perturbation strength is also derived. Fidelity decay in the perturbative and the FGR regimes are studied in Sect. V, with emphasis on the problems mentioned above. In the perturbative regime, the exponential fidelity decay before the Heisenberg time is shown numerically to coincide with the FGR decay in the sawtooth map. In the FGR regime, we revisit the non-FGR decay in the sawtooth map found in [28], and show numerically that the central part of the distribution of action difference can be approximated by the Levy distribution, which can explain some properties of the non-FGR decay. Section VI is devoted to a study of fidelity decay in the Lyapunov regime, when the average is performed over the logarithm of fidelity. Conclusions and discussions are given in Sect. VII.

II. MODELS: KICKED ROTATOR AND SAWTOOTH MAP

The Hamiltonians of the two models employed in this paper are of the forms,

$$H = \frac{1}{2}p^2 + V_{k(s)}(r) \sum_{n=0}^{\infty} \delta(t - nT) \quad \text{with (2)}$$

$$V_k(r) = K \cos r \quad \text{for kicked rotator, and (3)}$$

$$V_s(r) = -K(r - \pi)^2/2 \quad \text{(for sawtooth map). (4)}$$

For simplicity, the period T is set to be unit, $T = 1$. Kicks are switched on at $t = n$, $n = 0, 1, 2, \dots$. The classical map describing the kicked rotator is the standard map,

$$\begin{aligned} p_{n+1} &= p_n + K \sin(r_n) \pmod{2\pi}, \\ r_{n+1} &= r_n + p_{n+1} \pmod{2\pi}. \end{aligned} \quad (5)$$

The sawtooth map is

$$\begin{aligned} p_{n+1} &= p_n + K(r_n - \pi) \pmod{2\pi} \\ r_{n+1} &= r_n + p_{n+1} \pmod{2\pi}. \end{aligned} \quad (6)$$

Equation (6) can be rewritten in the matrix form,

$$\begin{pmatrix} p_{n+1} \\ r_{n+1} - \pi \end{pmatrix} = \begin{pmatrix} 1 & K \\ 1 & K+1 \end{pmatrix} \begin{pmatrix} p_n \\ r_n - \pi \end{pmatrix}, \quad (7)$$

where the 2×2 constant matrix possesses two eigenvalues $1 + (K \pm \sqrt{K^2 + 4K})/2$. At $K > 0$, motion in the sawtooth map is completely chaotic, with the Lyapunov exponent $\lambda = \ln\{(2 + K + [(2 + K)^2 - 4]^{1/2})/2\}$, given by the largest eigenvalue of the matrix. The finite-time Lyapunov exponent has the same value as the Lyapunov exponent λ defined in the limit $t \rightarrow \infty$. On the other hand, the standard map, which is chaotic at K larger than 6 or so, does not have a constant finite-time Lyapunov exponent, because the mapping matrix is a function of r_n . It is of interest to mention a recent result on the classical analog of fidelity, namely, for systems with

more than one dimensional configuration space the classical fidelity has a decaying rate related to not only the maximum Lyapunov exponent, but also other positive Lyapunov exponents [36].

The two classical systems are quantized on a torus [37, 38, 39, 40]. In a system with 1D finite configuration space, $0 \leq r < r_m$, and 1D finite momentum space, $0 \leq p < p_m$, the effective Planck constant $\hbar$ and the dimension N of the Hilbert space has the relation

$$N\hbar = r_m p_m. \quad (8)$$

In both models, we take $r_m = p_m = 2\pi$, hence, $\hbar = 2\pi/N$.

Floquet operators in the two quantized systems have the form

$$U = \exp[-i\hat{p}^2/(2\hbar)] \exp[-iV_{k(s)}(\hat{r})/\hbar]. \quad (9)$$

Eigenstates of $\hat{r}$ are denoted by $|j\rangle$, and $\hat{r}|j\rangle = j\hbar|j\rangle$, with $j = 0, 1, 2, \dots, N-1$. In this representation, elements of the operator U are

$$U_{j'j} = \frac{1}{\sqrt{N}} \exp \left[i \frac{\pi(j' - j)^2}{N} - i \frac{NV_{k(s)}(r_j)}{2\pi} - i \frac{\pi}{4} \right]. \quad (10)$$

The evolution of states, $\psi(t) = U^t \psi_0$, is calculated numerically by the fast Fourier transform (FFT) method.

The fidelity in Eq. (1) involves two slightly different Hamiltonians, H_0 and $H_1 = H_0 + \epsilon V$. In what follows, H_0 takes the form of H in Eq. (2), and

$$V = \frac{1}{K} V_{k(s)}(r) \sum_{n=0}^{\infty} \delta(t - nT), \quad (11)$$

except in Sect. IV B 2.

III. UNIFORM SEMICLASSICAL APPROACH TO FIDELITY

A. Approximation to fidelity with action expanded to the first order term

For the sake of completeness and convenience in presenting our results, we briefly recall the main results of the semiclassical approach to fidelity in Refs. [6, 22] in this section.

In the semiclassical approach, an initial state $\psi_0(\mathbf{r}_0)$ in a d -dimensional configuration space is propagated by the semiclassical Van Vleck-Gutzwiller propagator,

$$\psi_{\text{sc}}(\mathbf{r}; t) = \int d\mathbf{r}_0 K_{\text{sc}}(\mathbf{r}, \mathbf{r}_0; t) \psi_0(\mathbf{r}_0), \quad (12)$$

where $K_{\text{sc}}(\mathbf{r}, \mathbf{r}_0; t) = \sum_s K_s(\mathbf{r}, \mathbf{r}_0; t)$, with

$$K_s(\mathbf{r}, \mathbf{r}_0; t) = \frac{C_s^{1/2}}{(2\pi i \hbar)^{d/2}} \exp \left[\frac{i}{\hbar} S_s(\mathbf{r}, \mathbf{r}_0; t) - \frac{i\pi}{2} \mu_s \right]. \quad (13)$$

Here, the label s [more exactly $s(\mathbf{r}, \mathbf{r}_0; t)$] indicates classical trajectories starting from $\mathbf{r}_0$ and ending at $\mathbf{r}$ in a time t , the action $S_s(\mathbf{r}, \mathbf{r}_0; t)$ is the time integral of the Lagrangian along the trajectory s , $S_s(\mathbf{r}, \mathbf{r}_0; t) = \int_0^t dt' \mathcal{L}$, and $C_s = |\det(\partial^2 S_s / \partial r_{0i} \partial r_j)|$. μ_s is the Maslov index counting the conjugate points.

Consider an initial Gaussian wave packet centered at $\tilde{\mathbf{r}}_0$, with dispersion ξ and mean momentum $\tilde{\mathbf{p}}_0$,

$$\psi_0(\mathbf{r}_0) = \left(\frac{1}{\pi \xi^2} \right)^{d/4} \exp \left[\frac{i}{\hbar} \tilde{\mathbf{p}}_0 \cdot \mathbf{r}_0 - \frac{(\mathbf{r}_0 - \tilde{\mathbf{r}}_0)^2}{2\xi^2} \right]. \quad (14)$$

When ξ is small enough, within the effective domain of $\mathbf{r}_0$, $S_s(\mathbf{r}, \mathbf{r}_0; t)$ can be expanded in the Taylor expansion with respect to the center $\tilde{\mathbf{r}}_0$,

$$S_s(\mathbf{r}, \mathbf{r}_0; t) = S_s(\mathbf{r}, \tilde{\mathbf{r}}_0; t) - (\mathbf{r}_0 - \tilde{\mathbf{r}}_0) \cdot \mathbf{p}_s + \dots, \quad (15)$$

where

$$\mathbf{p}_s = - \left. \frac{\partial S_s(\mathbf{r}, \mathbf{r}_0; t)}{\partial \mathbf{r}_0} \right|_{\mathbf{r}_0 = \tilde{\mathbf{r}}_0} \quad (16)$$

is the initial momentum of the trajectory $s(\mathbf{r}, \tilde{\mathbf{r}}_0; t)$.

The semiclassical approximation to the fidelity amplitude $m(t)$ in Eq. (1) is

$$m(t) \simeq \int d\mathbf{r} [\psi_{\text{sc}}^{H_1}(\mathbf{r}; t)]^* \psi_{\text{sc}}^{H_0}(\mathbf{r}; t), \quad (17)$$

where the two states are propagated by the two Hamiltonians H_1 and H_0 , respectively. For quite small ξ , the expansion in Eq. (15) can be truncated at the first order term. Then, by using Eqs. (13)-(16) the integration on the right hand side of Eq. (12) is calculated.

The amplitude $m(t)$ thus obtained is [6],

$$m(t) \simeq m_{\text{sc1}}(t) \equiv \left(\frac{\xi^2}{\pi \hbar^2} \right)^{d/2} \times \int d\mathbf{r} \sum_s C_s \exp \left[\frac{i}{\hbar} \Delta S_s(\mathbf{r}, \tilde{\mathbf{r}}_0; t) - \frac{\xi^2}{\hbar^2} (\mathbf{p}_s - \tilde{\mathbf{p}}_0)^2 \right], \quad (18)$$

where $\Delta S_s(\mathbf{r}, \tilde{\mathbf{r}}_0; t)$ is the action difference for the two trajectories with the same label s in the two systems H_1 and H_0 . In the first order classical perturbation theory, the difference between the two trajectories s is assumed negligible,

$$\Delta S_s(\mathbf{r}, \tilde{\mathbf{r}}_0; t) \simeq \epsilon \int_0^t dt' V[\mathbf{r}(t')] \quad (19)$$

with V evaluated along the trajectory.

A simpler expression of $m(t)$ can be obtained by changing the variable $\mathbf{r} \rightarrow \mathbf{p}_0$ [22],

$$m_{\text{sc1}}(t) = \left(\frac{\xi^2}{\pi \hbar^2} \right)^{d/2} \times \int d\mathbf{p}_0 \exp \left[\frac{i}{\hbar} \Delta S(\mathbf{p}_0, \tilde{\mathbf{r}}_0; t) - \frac{(\mathbf{p}_0 - \tilde{\mathbf{p}}_0)^2}{(\hbar/\xi)^2} \right], \quad (20)$$

where $\Delta S(\mathbf{p}_0, \tilde{\mathbf{r}}_0; t)$ coincides with $\Delta S_s(\mathbf{r}, \tilde{\mathbf{r}}_0; t)$ for the same trajectory s with initial momentum $\mathbf{p}_0$. The main contribution to the right hand side of Eq. (20) comes from a window in the $\mathbf{p}_0$ space, which is centered at $\tilde{\mathbf{p}}_0$ and has a size of the order $\hbar/\xi$.

For a system with finite momentum space, Eq. (20) is invalid for initial Gaussian wave packets that are wide in the momentum space. The extreme case is for initial point sources, $\langle \mathbf{r} | \Psi_0 \rangle = \sqrt{(2\pi\hbar)^d / \mathcal{V}_p} \delta(\mathbf{r} - \mathbf{r}_0)$, with $\mathcal{V}_p$ being the volume of the momentum space. In this case [28],

$$m(t) \simeq m_p(\mathbf{r}_0, t) \equiv \frac{1}{\mathcal{V}_p} \int d\mathbf{p}_0 \exp \left[\frac{i}{\hbar} \Delta S(\mathbf{p}_0, \mathbf{r}_0; t) \right]. \quad (21)$$

The above semiclassical expressions of $m(t)$ suggests introducing

$$\sigma = \epsilon / \hbar, \quad (22)$$

as a quantum perturbation parameter.

B. Contribution to fidelity from the second order term in action expansion

Hereafter we restrict our discussions to 1-dimensional kicked systems. In deriving Eq. (20) for fidelity of an initial Gaussian wave packet, the right hand side of Eq. (15) is truncated at the first order term. Hence, Eq. (20) is valid only when $\xi^2 \ll \hbar$, or $\kappa \gg 1$ with the parameter κ defined by

$$\kappa \equiv \hbar / \xi^2, \quad (23)$$

which has been confirmed in our numerical calculation.

When the condition $\kappa \gg 1$ is not satisfied, high order terms on the right hand side of Eq. (15) may give considerable contribution. Indeed, numerically, obvious deviation of $M_{\text{sc1}}(t) = |m_{\text{sc1}}(t)|^2$ from the exact $M(t)$ has been observed at κ close to one or smaller (see Fig. 1 for an example). We remark that numerical evaluation of the right hand side of Eq.(20) for $m_{\text{sc1}}(t)$ becomes more and more difficult with increasing t , because the number of the oscillation of $\Delta S(p_0, \tilde{r}_0; t)$ versus p_0 increases exponentially [30].

To have a good semiclassical approximation at $\kappa \sim 1$, one needs to consider the second order term on the right hand side of Eq. (15),

$$S_s(r, r_0; t) \simeq S_s(r, \tilde{r}_0; t) - (r_0 - \tilde{r}_0)p_s - \frac{1}{2} \frac{\partial p_s}{\partial \tilde{r}_0} (r_0 - \tilde{r}_0)^2, \quad (24)$$

where

$$\frac{\partial p_s}{\partial \tilde{r}_0} \equiv \left. \frac{\partial p_s}{\partial r_0} \right|_{r_0=\tilde{r}_0} = - \left. \frac{\partial^2 S_s(r, r_0; t)}{\partial r_0^2} \right|_{r_0=\tilde{r}_0}. \quad (25)$$

FIG. 1: Comparison of the exact values of a single fidelity $M(t)$ and their semiclassical approximations $M_{\text{sc1}}(t)$ in Eq. (20) and $M_{\text{sc2}}(t)$ in Eq. (26), in the kicked rotator model. Parameters are $K = 10$, $N = 2^{17} = 131072$, $\sigma = 1$, and $\kappa = 1$. The typical value of D in Eq. (27) is about $8.9 \gg 1$, explaining the deviation of $M_{\text{sc1}}(t)$ from the exact values, while $M_{\text{sc2}}(t) = |m_{\text{sc2}}(t)|^2$ being quite close to the exact ones.

Using Eq. (24) and following a procedure similar to the derivation of Eq. (20), we obtain

$$m_{\text{sc2}}(t) = \int dp_0 \frac{\xi}{\sqrt{\pi} \hbar D} \exp \left[\frac{i}{\hbar} \Delta S(p_0, \tilde{r}_0; t) - \frac{(p_0 - \tilde{p}_0)^2}{(\hbar D / \xi^2)^2} \right], \quad (26)$$

where

$$D = \sqrt{1 + \frac{1}{\kappa^2} \left(\frac{\partial p_s}{\partial \tilde{r}_0} \right)^2}. \quad (27)$$

Note that D is a function of $p_0, \tilde{r}_0$ and t . A numerical test for this modified semiclassical approximation is shown in Fig. 1.

Comparing the two equations (20) and (26), it is seen that the modification is to replace $(\hbar/\xi)$ in Eq. (20) by

$$w_p = \frac{\hbar}{\xi} D = \sqrt{\frac{\hbar^2}{\xi^2} + \xi^2 \left(\frac{\partial p_s}{\partial \tilde{r}_0} \right)^2}, \quad (28)$$

i.e., the change in the size of the effective window for integration. Therefore, the modified semiclassical expression in Eq. (26) predicts the same long-time decaying behaviors of fidelity as Eq. (20), more precisely, the same decaying rate for the FGR decay in the FGR regime, and the same $\Lambda_1(t)$ decay in the Lyapunov regime (cf. Sect. VI).

When the value of κ decreases further, higher order terms in the Taylor expansion of the action should be considered, e.g., at $\xi^3 \sim \hbar$, the third order term should be taken into account.

FIG. 2: Variation of $\Delta S(p_0, r_0; t)/2\pi\epsilon$ versus $p_0/2\pi$ in the sawtooth map at $K = 1$, for a value of r_0 taken randomly within $[0, 2\pi)$. $r(t)$ is the position r at time t , with initial condition (r_0, p_0) . For clarity, r is plotted as a continuous function of p_0 , by adding $2n\pi$ at the discontinuous points.

IV. SHORT TIME BEHAVIOR OF FIDELITY

The behavior of fidelity in short times is initial-state-dependent. In this section, we discuss short-time-decay of fidelity of initial Gaussian wave packets and of initial point sources.

A. Oscillation of $\Delta S(p_0, r_0; t)$ versus p_0

The semiclassical expressions of fidelity discussed in the previous section, specifically, Eqs. (20), (21) and (26), show that decaying behavior of $M(t)$ is mainly determined by the action difference $\Delta S(p_0, r_0; t)$ as a function of p_0 . Therefore, before addressing fidelity decay, it is useful to first discuss an important property of the action difference, namely, its oscillation as a function of p_0 .

The number of the oscillations of ΔS , as p_0 runs over $[0, 2\pi)$, increases exponentially with time t . To see this, using Eq. (19), we write the slope of $\Delta S/\epsilon$, denoted by

FIG. 3: Same as Fig. 2 but for the standard map of $K = 10$.

k_p , in the following explicit form,

$$k_p \equiv \frac{1}{\epsilon} \frac{\partial \Delta S(p_0, r_0; t)}{\partial p_0} \simeq \int_0^t dt' \frac{\partial V}{\partial r'} \frac{\partial r'(t')}{\partial p_0}, \quad (29)$$

where the dependence of k_p on p_0, r_0 and t is not written explicitly, for brevity. Due to the underlying chaotic classical dynamics, $|\partial r'(t')/\partial p_0|$ increases exponentially with t' , on average. On the other hand, the variance of ΔS increases as t [10], hence, the typical value of $|\Delta S|$ increases as $\sqrt{t}$. Therefore, the number of the oscillations of ΔS must increase exponentially with t . The fast oscillation of ΔS is crucial for understanding the long time decay of fidelity in the Lyapunov regime [28, 30].

We present some examples of the oscillating behavior of ΔS in the sawtooth map (Fig. 2), as well as some in the kicked rotator model (Fig. 3). The two models have different dependence of the position $r(t)$ on the initial momentum p_0 at fixed time t . Specifically, in the sawtooth map, r is a linear function of p_0 except at the discontinuous points, with the slope given by the constant local Lyapunov exponent, while in the kicked rotator, it is an oscillating function.

B. Time scales τ_1 and τ_2 for fidelity of initial Gaussian wave packets

Fidelity of initial narrow Gaussian wave packets has rich behavior at short times. For example, there are both very fast and quite slow decays at the first several kicks in the deep Lyapunov regime [20], as well as a decay with

a rate of twice the Lyapunov exponent [30]. By using the uniform semiclassical approach discussed above, we give a unified description for these phenomena in this section.

1. Time interval $t < \tau_1$

The main contribution to the right hand side of Eq. (26) comes from a narrow window in the p_0 space. For time t short enough, linear approximation can be used for the action difference ΔS within the narrow window. This suggests the introduction of a time scale, denoted by τ_1 , such that for $t < \tau_1$ linear approximation of ΔS can be used in calculating the right hand side of Eq. (26),

$$\Delta S(p_0, \tilde{r}_0; t) \simeq \Delta S(\tilde{p}_0, \tilde{r}_0; t) + \epsilon \tilde{k}_p(p_0 - \tilde{p}_0), \quad (30)$$

where $\tilde{k}_p$ is the value of k_p in Eq. (29) at the center $(\tilde{r}_0, \tilde{p}_0)$ of the initial Gaussian packet.

To give an estimation to τ_1 , we use $\Delta p_0(t)$ to denote the size of the region in the p_0 space, which is capable of the above linear approximation for ΔS . One should note that $\Delta p_0(t)$ shrinks exponentially, due to the exponentially increasing of the number of oscillations of ΔS versus p_0 . Since the oscillation of ΔS is mainly induced by local instability of trajectories, $\Delta p_0(t)$ shrinks roughly as $e^{-\Lambda(t)t}$, where

$$\Lambda(t) = \lim_{\delta x(0) \rightarrow 0} \frac{1}{t} \frac{|\ln |\delta x(t)/\delta x(0)||}{}, \quad (31)$$

with $\delta x(t)$ denoting distance in phase space and average performed over phase space. (In a classical system with strong chaos, $\Lambda(t)$ usually approaches the Lyapunov exponent λ quickly, as will be illustrated numerically in Sect. VI.) Then,

$$\Delta p_0(t) \simeq b(t) \Delta p_0(1) e^{-\Lambda(t) \cdot (t-1)}, \quad (32)$$

where $b(t)$ is the influence of other factors, such as the variance of ΔS increasing linearly with t , and changes much slower than the exponential term. At time τ_1 , we write

$$\Delta p_0(\tau_1) = a_1 w_p, \quad (33)$$

where $a_1 > 1$ is determined by the accuracy required.

Substituting Eq. (32) into Eq. (33) for $t = \tau_1$, we obtain

$$\tau_1 \sim 1 + \frac{1}{\Lambda(\tau_1)} \ln \frac{\bar{b} \Delta p_0(1)}{a_1 w_p}, \quad (34)$$

where $\bar{b}$ is the average value of $b(t)$ for small t . Several points can be seen in Eq. (34). Firstly, since $\Delta p_0(1)$ decreases with increasing σ , when σ is large enough, the right hand side of Eq. (34) can be smaller than 1, implying $\tau_1 = 0$. Secondly, for large enough τ_1 such

that $\Lambda(\tau_1) \simeq \lambda$, the dependence of τ_1 on $\hbar$ is given by $(1/2\lambda) \ln \hbar^{-1}$ for $\xi = \hbar^{1/2}$, which is half the Ehrenfest time.

When the change of D is negligible within the effective narrow window of p_0 , in which the linear approximation for ΔS in Eq. (30) can be used, substituting Eq. (30) into Eq. (26), we have

$$M_{sc2}(t) \simeq \exp \left[-\frac{1}{2} \left(\sigma w_p \tilde{k}_p \right)^2 \right], \quad t < \tau_1, \quad (35)$$

with the time dependence on the right hand side given by $\tilde{k}_p(\tilde{r}_0, \tilde{p}_0; t)$.

Due to exponential divergence of neighboring trajectories in phase space, the main contribution to the right hand side of Eq. (29) comes from times $t \approx t'$. Therefore, $|\tilde{k}_p|$ increases typically as $c_k e^{\Lambda(t)t}$, with c_k being the pre-factor. For this time dependence of $|\tilde{k}_p|$, Eq. (35) predicts

$$M_{sc2}(t) \simeq \exp \left[-\frac{1}{2} w_p^2 c_k^2 (\epsilon/\hbar)^2 e^{2\Lambda(t)t} \right], \quad t < \tau_1. \quad (36)$$

This gives the extremely fast, double-exponential-rate decay of fidelity predicted in Ref. [20], $M(t) \simeq \exp(-\text{const} \times e^{2\lambda t})$, when $\Lambda(t) \sim \lambda$. Note that our prediction (35) is more general, since it works for small values of $|\tilde{k}_p|$ as well, so long as $\tilde{p}_0$ is not quite close to any stationary point, which may invalid the approximation in Eq. (30).

Numerical check of our prediction (35) is shown in Fig. 4 for the first kick. For $\sigma < 40$, the analytical results have good agreement with the exact numerical calculations. With increasing σ , deviation enlarges, with $M_{sc}(t) < M(t)$, because the difference between the exact values of the phase $\Delta S/\hbar$ and their linear approximations increases linearly with σ .

2. Time interval $\tau_1 < t < \tau_2$

For $t > \tau_1$, the main contribution to the right hand side of Eq. (26) comes from the integration over the region $[\tilde{p}_0 - w_p, \tilde{p}_0 + w_p]$. It is useful to introduce a second time scale, denoted as τ_2 , at which $\Delta S(p_0, \tilde{r}_0; t)$ completes one full oscillation period as p_0 runs over $[\tilde{p}_0 - w_p, \tilde{p}_0 + w_p]$ [30]. Note that $\tau_1 < \tau_2$, according to their definitions.

In order to estimate the time τ_2 , we note that the number of oscillations of ΔS increases as $e^{\Lambda(t)t}$, then, τ_2 satisfies the following relation

$$\bar{\tau}_2 \approx \frac{1}{\Lambda(\bar{\tau}_2)} \ln \left(\frac{\pi}{c_0 w_p} \right). \quad (37)$$

When $\Lambda(\bar{\tau}_2) \simeq \lambda$, this relation gives the estimation

$$\bar{\tau}_2 \approx \frac{1}{\lambda} \ln \left(\frac{\pi}{c_0 w_p} \right). \quad (38)$$

FIG. 4: Comparison of the exact values of $M(t)$ and the semiclassical prediction given by Eq. (35) at the first kick $t = 1$, for one initial Gaussian wave packet, in the kicked rotator model with $K = 10$, $\kappa = 1$.

The time scale τ_2 is important in understanding short-time decay of fidelity in the deep Lyapunov regime with $\sigma \gg 1$. Indeed, in the time interval $\tau_1 < t < \tau_2$, the phase $(\Delta S/\hbar)$ on the right hand side of Eq. (26), as a function of p_0 , can usually be approximated by a straight line within the region $p_0 \in [\tilde{p}_0 - w_p, \tilde{p}_0 + w_p]$. Then, for initial states satisfying $|\sigma \tilde{k}_p| \gg \pi/w_p$, one has [30],

$$M_{sc}(t) \propto 1/(\sigma \tilde{k}_p)^2, \quad \tau_1 < t < \tau_2. \quad (39)$$

To be more specific, let us consider a special kind of system, which has constant local Lyapunov exponent λ in the classical limit and has no stationary point of ΔS , i.e., $k_p \neq 0$ for all p_0 . For such systems, $\Lambda(t) = \lambda$. As shown in [30], when the smallest $|k_p|$ are so large that Eq. (39) is applicable for all initial states, the average fidelity has a decay with a rate of twice the Lyapunov exponent,

$$\overline{M}(t) \propto e^{-2\lambda t}, \quad (40)$$

since k_p increases as $e^{\lambda t}$ on average. Here we are interested in the general situation, in which the smallest $|k_p|$ are not large enough for the applications of Eq. (39), i.e., when $|\sigma \tilde{k}_p| \gg \pi/w_p$ is not satisfied for $|\tilde{k}_p|$ close to its smallest value. In this general case, the average fidelity has a decay rate smaller than 2λ due to the influence the small $|k_p|$. On the other hand, we note that the size of the region of p_0 with quite small $|k_p|$ decreases exponentially, due to the exponential increment of the number of oscillation of ΔS , therefore, the decay rate of the average fidelity should be larger than λ .

To verify numerically the above prediction of fidelity decay between $e^{-\lambda t}$ and $e^{-2\lambda t}$ for $\tau_1 < t < \tau_2$, we use the sawtooth map, with the following form of the perturba-

FIG. 5: Same as Fig. 2 but for the sawtooth map with perturbations in Eq. (41) and $t = 2$.

tion V (H_0 unchanged) [30],

$$V^{(i)} = V^{(i)}(r) \sum_{n=0}^{\infty} \delta(t - nT) \quad \text{where} \quad (41)$$

$$V^{(i)}(r) = -\mathcal{N}_i(r - \pi)^i, \quad i = 1, 2, 3, 4, 5. \quad (42)$$

Setting the coefficient $\mathcal{N}_2 = 1/2$, $V^{(2)}$ gives the perturbation in Eq. (11), which are also used in [17, 28]. The other coefficients $\mathcal{N}_i$ are chosen by the requirement of having the same decaying rate in the FGR regime, i.e., possessing the same value of the classical action diffusion constant $K(E)$ [10]. For kicked maps, $K(E)$ has the form [41, 42],

$$K(E) = \frac{1}{2}C(0) + \sum_{l=1}^{\infty} C(l), \quad \text{where} \quad (43)$$

$$C(l) = \langle \{V[r(l)] - \langle V \rangle\} \{V[r(0)] - \langle V \rangle\} \rangle \quad (44)$$

with the average performed over phase space.

At integer values of K in the sawtooth map in Eq. (4), simple derivation shows that $C(l) = 0$ for $l \neq 0$ and

$$C(0) = \begin{cases} \frac{1}{2i+1} \mathcal{N}_i^2 \pi^{2i}, & (\text{odd } i); \\ \frac{i^2}{(2i+1)(i+1)^2} \mathcal{N}_i^2 \pi^{2i}, & (\text{even } i). \end{cases} \quad (45)$$

Then,

$$\mathcal{N}_1 = \frac{\pi}{\sqrt{15}}, \quad \mathcal{N}_3 = \frac{\sqrt{1.4}}{3\pi}, \quad \mathcal{N}_4 = \frac{\sqrt{5}}{4\pi^2}, \quad \mathcal{N}_5 = \frac{\sqrt{2.2}}{3\pi^3}. \quad (46)$$

For the sawtooth map with the above perturbation, the action difference at time t can be written as

$$\Delta S \simeq -\epsilon \sum_{n=0}^{t-1} \mathcal{N}_i [r(n) - \pi]^i. \quad (47)$$

FIG. 6: Values of k_p of a r_0 chosen randomly, in the sawtooth map with perturbation $V^{(i)}$ of $i = 3$ and 5 , $t = 3$.

It is easy to prove, by using Eq. (6), that $r(n)$ for any fixed n is a monotonically increasing function of p_0 , except at the discontinuous changes from 0 to 2π (or reversely). Then, Eq. (47) shows that no point exists at which $k_p = 0$ for odd i , while k_p can be zero for even i . (See Figs. 2 and 5 for some examples of numerical illustrations.) Therefore, in the time interval $\tau_1 < t < \tau_2$, $\bar{M}(t)$ should have the standard Lyapunov decay for even i [30] and faster than Lyapunov decay for odd i .

Some values of $|k_p|$ for $V^{(i)}$ of $i = 3$ and 5 are presented in Fig. 6. It is seen that some k_p for $i = 5$ are quite close to zero, implying a decay rate of fidelity between λ and 2λ in the time interval (τ_1, τ_2) for $i = 5$; on the other hand, the smallest $|k_p|$ for $i = 3$ is not quite close to zero, implying a decay rate of 2λ . Indeed, these predictions have been confirmed in a direct calculation of $M(t)$, as shown in Fig. 7. The values of τ_1 and τ_2 can be estimated as follows. At $K = 1$ and $\xi = \sqrt{\hbar}$, numerical computation shows that $c_0 \simeq 0.45$ and $D \simeq 1.9$. We take $\Delta p_0(1) \sim 2\pi/100$ for $\sigma = 100$ (cf. Fig. 2 for variation of $\Delta S/\epsilon$ at $t = 1$), $a_1 \sim 5$, $\bar{b} \sim 1$, then, Eq. (34) gives $\bar{\tau}_1 \sim 1$. Meanwhile, Eq. (38) gives $\bar{\tau}_2 \approx 6.5$. The two estimations are in good agreement with the direct numerical results shown in Fig. 7.

C. Dependence of first-kick-decay of fidelity on perturbation strength for initial point sources

Fidelity of initial point sources, described by Eq. (21) with integration performed over the whole p_0 domain, has a short-time decay different from that of initial Gaussian wave packets discussed above.

In the FGR regime, fidelity can be calculated by writing the right hand side of Eq. (21) in terms of the distribution of ΔS (see Refs. [10, 28]). When the distribution of ΔS is close to the expected Gaussian distribution, one

FIG. 7: Decay of the averaged fidelity in the sawtooth map with $K = 1$, for $V^{(i)}$ of $i = 1, 3, 4, 5$ in Eq. (41), with parameters $\sigma = 100$, $N = 131072$, $\xi = \sqrt{\hbar}$. For these parameters, $\bar{\tau}_1 \sim 1$ and $\bar{\tau}_2 \approx 6.5$. In the time interval $\tau_1 < t < \tau_2$, the average fidelity has the Lyapunov decay for $i = 4$, a double-Lyapunov decay for $i = 3$, and a decay between the two decays for $i = 5$. The quite fast decay for $i = 1$ is due to the linear dependence of ΔS on p_0 , as shown in Fig. 5. Averages are performed over 2000 initial Gaussian packets, with centers taken randomly with flat distribution in the region $\pi/2 \leq \tilde{r}_0(\tilde{p}_0) < 3\pi/2$.

has the FGR decay for fidelity,

$$M_{\text{FGR}}(t) \simeq \exp[-2\sigma^2 K(E)t], \quad (48)$$

where $K(E)$ is the classical action diffusion constant in Eq. (43).

In the deep Lyapunov regime, Eq. (21) enables an estimation to the dependence of fidelity on perturbation strength, which is $1/\sigma$, as shown in Eq. (A4) in Appendix A. Since this dependence does not change with time, it can be seen at the first kick only. For systems with constant local Lyapunov exponents, combining Eq. (A4) and the known Lyapunov decay, we have

$$\bar{M}_p(t) \propto \frac{1}{\sigma} \exp(-\lambda t). \quad (49)$$

Figure 8 presents an example of numerical confirmation to the above predictions for the first-kick decay of fidelity.

FIG. 8: Decay of fidelity $M(t)$ at the first kick $t = 1$ as a function of σ , for a single initial point source, in the logarithm scale. It shows a FGR behavior for small σ and a $1/\sigma$ dependence for large σ . $M_{\text{FGR}}(t) \simeq e^{-2.2\sigma^2 t}$ in the sawtooth map with $K_0 = 1$.

V. THE PERTURBATIVE AND THE FGR REGIMES

In this Section, we study fidelity decay before the Heisenberg time in the perturbative regime, and the influence of weak chaos on fidelity decay in the FGR regime.

A. The perturbative regime

The regime of quite small ϵ , more precisely, quite small σ , is named the perturbative (PT) regime, in which fidelity has a Gaussian type decay [9, 10, 16]. Combining the perturbation theory, the random matrix theory (RMT), and the semiclassical theory, it has been found that

$$M_{\text{PT}}(t) \simeq \exp\left(-\frac{2gK(E)}{\pi\bar{d}\beta}\sigma^2 t^2\right), \quad (50)$$

for quantized maps, where $2g/\beta$ is the number of classical orbits with identical action, which is 2 for the models used here, and $\bar{d}$ is the total mean density of states. The index $\beta = 1$ for time-reversal-invariant systems and $\beta = 2$ for time-reversal-breaking systems. (Cf. Ref. [16] for the expression for continuous variables.)

The Gaussian decay (50) sets in at about the Heisenberg time $t_H \approx N$. For t short enough compared with t_H , there is no reason for the semiclassical approach to fail in describing the fidelity decay, even for quite small σ . Therefore, it is reasonable to expect the FGR decay in Eq. (48) for fidelity in the perturbative regime, before some time shorter than t_H . In fact, numerically, fidelity has been found to possess an exponential decay in the

FIG. 9: Decay of the averaged fidelity in the perturbative regime of the sawtooth map at $K = 1$, $N = 512$, and $\sigma = 10^{-5}$. Average is performed over 100 initial point sources taken randomly in the configuration space. The decay follows the FGR decay approximately up to $t \sim 400$.

kicked rotator model, before some time shorter than the Heisenberg time t_H [22]. Whether this exponential decay is the FGR decay or not is unclear, since the value of $K(E)$ in this model is calculated only approximately.

To make the situation clearer, we employ the sawtooth map, in which the value of $K(E)$ can be computed analytically for integer values of the parameter K in its Hamiltonian, $K(E) = \pi^4/90 \simeq 1.08$ [see Eq. (45)]. Numerical results indeed support the above argument that fidelity has the FGR decay, before a time shorter than the Heisenberg time (see Fig. 9).

Deviation of fidelity decay from the FGR decay in the perturbative regime, provides a good opportunity for a numerical study of the breakdown time of the semiclassical approach, denoted by t_B . It is known that t_B is proportional to some inverse algebraic power of $\hbar$ [43, 44, 45, 46]. In the sawtooth map, it was found that t_B is linear in $1/\hbar$, more exactly, $t_B \approx 0.8N \propto \hbar^{-1}$, as seen in Fig. 10.

B. The FGR regime

When the perturbation parameter σ is large enough, $M(t)$ becomes close to its saturation value, which is proportional to $1/N$ [15], before the Gaussian decay sets in at about the Heisenberg time, then, one enters into the FGR regime. The perturbation border for the crossover from the perturbative regime to the FGR regime can be estimated as [10]

$$\sigma_p = \frac{\epsilon_p}{\hbar} \sim \sqrt{\frac{\ln N}{2K(E)N}}. \quad (51)$$

For systems possessing strong chaos in the classical

FIG. 10: The breakdown time t_B of the semiclassical approach versus the dimension N of the Hilbert space, in the logarithmic scale for the sawtooth map with $K = 1$, at different values of σ . In numerical calculation, t_B is taken as the first kick at which the relative error $|[M(t) - M_{\text{FGR}}(t)]/M(t)|$ is larger than 0.1, where $M_{\text{FGR}}(t)$ is the FGR decay in Eq. (48) predicted by the semiclassical theory.

limit, two analytical approaches are available to obtain the FGR decay, namely, the semiclassical approach with the assumption of a Gaussian type distribution of ΔS [10], which gives the result in Eq. (48), and the RMT approach making use of the closeness between the form of the LDOS and the Lorentzian distribution [7, 9]. The two approaches are believed to be equivalent, when both are valid; while an analytical proof of the equivalence is available only in some special cases [8]. An interesting phenomenon is that the two approaches are complementary in some cases. For example, for quite short time t , there is no analytical reason for the distribution of ΔS to be close to a Gaussian distribution, while the RMT approach can be used in deriving the FGR decay. On the other hand, for t relatively long (but shorter than t_B), the semiclassical approach works well, while the RMT approach may meet the problem of deviation of the LDOS from the Lorentzian form in the tail region, which is a result of the finite domain of the quasi-energy spectrum [19].

When the underlying classical dynamics has weak chaos, non-FGR decay of fidelity may appear in the expected FGR regime, due to obvious deviation of the distribution of ΔS from the expected Gaussian distribution [28]. For this kind of systems, the RMT approach does not give a correct prediction for fidelity decay, while the semiclassical approach still works.

In the semiclassical approach, one can separate the average fidelity into a mean-value part and a fluctuating part, denoted by $\overline{M}_a(t)$ and $\overline{M}_f(t)$, respectively, $\overline{M}(t) \equiv |\overline{m}(t)|^2 = \overline{M}_a(t) + \overline{M}_f(t)$, where

$$\overline{M}_a(t) \equiv |\overline{m}(t)|^2, \quad (52)$$

FIG. 11: Decay rate γ of fidelity versus perturbation strength σ , calculated by the best fit of $-\gamma t$ to $\ln \overline{M}(t)$, for some values of the parameter K in the sawtooth map. In the calculation of average fidelity, 1000 randomly chosen Gaussian wave packets are used as initial states. The solid curve shows the rate $\Gamma \simeq 2.2\sigma^2$ of the FGR-decay. $N = 131072$, $\xi = \sqrt{\hbar}$.

with average performed over initial states. In the FGR regime, the average fidelity is approximately given by the mean-value part $\overline{M}_a(t)$, with $\overline{M}_f(t) \ll \overline{M}_a(t)$ [28]. The mean-value part $\overline{M}_a(t)$ can be expressed in terms of the distribution $P(\Delta S)$ of the action difference ΔS ,

$$\overline{M}_a(t) \simeq \left| \int d\Delta S e^{i\Delta S/\hbar} P(\Delta S) \right|^2, \quad \text{where} \quad (53)$$

$$P(\Delta S) = \frac{1}{\int d\mathbf{r}_0 d\mathbf{p}_0} \int d\mathbf{r}_0 d\mathbf{p}_0 \delta[\Delta S - \Delta S(\mathbf{p}_0, \mathbf{r}_0; t)] \quad (54)$$

In case of weak chaos, a general analytical expression for the distribution of ΔS is still absent. Since Gaussian distribution is invalid in this case, it is natural to study the possibility of Levy distribution. Due to its infinite variance, Levy distribution cannot describe the distribution of ΔS in the long tail region. Therefore, we focus on the central part and short tail region of the distribution of action difference, which give the main contribution to the mean-value part $\overline{M}_a(t)$ of fidelity.

We consider the following asymmetric form of Levy distribution [47],

$$L(x, \alpha, \beta) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(izx) \psi(z) dz, \quad (55)$$

with $x = \Delta S/\epsilon$. Here the function $\psi(z)$ is

$$\psi(z) = \exp\{-igz - D_t|z|^\alpha[1 + i\beta \operatorname{sgn}(z) \omega(z, \alpha)]\}, \quad (56)$$

$$\text{where} \quad \omega(z, \alpha) = \tan(\pi\alpha/2) \quad \text{for } \alpha \neq 1, \quad (57)$$

$$\omega(z, \alpha) = (2/\pi) \ln|z| \quad \text{for } \alpha = 1. \quad (58)$$

The parameter α , with $0 < \alpha < 2$, determines the decay of long tails, i.e., $L(x) \sim |x|^{-(1+\alpha)}$ for large $|x|$. The parameter β has the domain $[-1, 1]$, with $\beta = 0$ giving the

FIG. 12: Distribution $P[(\Delta S - \langle \Delta S \rangle)/\epsilon]$ of the classical action difference ΔS at $t = 10$, for $K = 0.4$ in the sawtooth map, calculated by taking randomly 10^7 initial points in the phase space. Here $\langle \Delta S \rangle \equiv \epsilon t \langle V \rangle = -\pi^2 \epsilon t / 6$, with average performed over the phase space. The solid curve is a fit given by the Levy distribution in Eq. (55), with $\alpha = 1$, and β and D_l as two fitting parameters.

symmetric distribution, g gives a shift along the x direction, and D_l is related to the width of the distribution. If the Levy distribution can be used as an approximation for $P(\Delta S)$, substituting Eq. (55) into Eq. (53), one obtains,

$$\overline{M}_a(t) \propto \exp(-2D_l \sigma^\alpha), \quad (59)$$

with the time dependence given by that of D_l . Note that a Gaussian form of $P(\Delta S)$ corresponds to $\alpha = 2$, giving the well known dependence on σ in the FGR decay.

It is known that the sawtooth map has weak chaos at $K < 1$ and has Cantori structures at K small [35]. Non-FGR decay has been observed in this model, which can still be described by Eq. (53) [28]. Therefore, we use this model to study the possibility of using the Levy distribution as an approximation to the distribution $P(\Delta S)$.

Numerically we use $-\gamma t$ to fit $\ln \overline{M}(t)$, in order to calculate the decay rate γ of fidelity. Variation of γ versus σ is presented in Fig. 11 for some values of K between 0.1 and 0.9, before the Lyapunov regime is reached. (The fidelity has been found to have the Lyapunov decay in the Lyapunov regime, for $K < 1$ [28].) As seen in the Figure, for $K = 0.1, 0.2$, and 0.4 , there exist some regions of σ , respectively, in which γ increases approximately linearly with σ . According to Eq. (59), this implies that $\alpha \simeq 1$, if the Levy distribution can be used as an approximation to $P(\Delta S)$. Figure 12 shows a fit of the Levy distribution to the central part and short tails of the distribution $P(\Delta S)$ at $K = 0.4$, with $\alpha = 1$ fixed and D_l and β used as two adjusting parameters. The agreement is encouraging, for which an analytical explanation is still not yet available and deserves a further investigation.

VI. THE LYAPUNOV REGIME

Increasing the perturbation strength further, one enters into the Lyapunov regime, in which the average fidelity has the Lyapunov decay $e^{-\lambda t}$ [6], in the special situation with negligible fluctuation in the finite-time Lyapunov exponent. In the general situation, the fluctuation of the finite-time Lyapunov exponent is not negligible, and the average fidelity has a $\Lambda_1(t)$ decay [30], which is usually different from the Lyapunov decay. The $\Lambda_1(t)$ decay will be discussed briefly in Sect. VIA, starting from the modified semiclassical approximation to fidelity in Eq. (26).

As mentioned in the introduction, in the kicked top model that has large fluctuation in the finite-time Lyapunov exponent, numerical results show that the average of the logarithm of fidelity has roughly the Lyapunov decay [19]. In Sect. VIB, we explain this phenomenon by using the technique developed in [30].

A. $\Lambda_1(t)$ decay of average fidelity in the deep Lyapunov regime

Since Eq. (26) can be obtained from Eq. (20) by replacing $\hbar/\xi$ with $w_p = \hbar D/\xi$, generalization of the results in [30] is straightforward. In this Section, we present the main points in the generalization, because part of them will be used in Sect. VIB.

For systems in which ΔS has stationary points with $k_p = 0$, we denote by α the stationary points of ΔS and by $p_{0\alpha}$ the momenta at which $k_p = 0$. When $\sigma \gg 1$, stationary phase approximation can be used in calculating the right hand side of Eq. (26), which gives

$$m_{sc}(t) \simeq \sum_{\alpha} m_{\alpha}(t), \quad \text{where} \quad (60)$$

$$m_{\alpha}(t) = \frac{\sqrt{2i\hbar} \exp \left[\frac{i}{\hbar} \Delta S(p_{0\alpha}, \tilde{r}_0; t) - (p_{0\alpha} - \tilde{p}_0)^2 / w_p^2 \right]}{w_p \sqrt{|\Delta S''_{\alpha}|}}, \quad (61)$$

with $\Delta S''_{\alpha} = \left. \frac{\partial^2 \Delta S(p_0, \tilde{r}_0; t)}{\partial p_0^2} \right|_{p_0=p_{0\alpha}}$.

Note that w_p in Eq. (61) takes the value at the stationary point α , with D being a function of $p_{0\alpha}$.

Let us consider time $t > \tau_2$, for which there are one or more stationary points within the effective window in the p_0 space for the integration on the right hand side of Eq. (26). Similar results can also be obtained for $t < \tau_2$, when the stationary phase approximation is applicable, as discussed in [30]. The average fidelity in the ordinary sense, with average performed over both $\tilde{r}_0$ and $\tilde{p}_0$, can be calculated by using diagonal approximation, when $\sigma \gg 1$ [28], and the following result is obtained

$$\overline{M}(t) \propto I_s(t) := \int d\tilde{r}_0 \int_{\mathcal{P}_{\delta}} dp_0 \frac{1}{D|k_p|}, \quad (62)$$

where $\mathcal{P}_\delta := \bigcup_\alpha \mathcal{A}_\alpha$. Here, $\mathcal{A}_\alpha$ denotes the region $[p_{0\alpha}^-, p_{0\alpha} + \delta] \cup [p_{0\alpha} + \delta, p_{0\alpha}^+]$, where $p_{0\alpha}^- = (p_{0\alpha} + p_{0,\alpha-1})/2$, $p_{0\alpha}^+ = (p_{0\alpha} + p_{0,\alpha+1})/2$, with δ being a small quantity.

The main contribution to the integral on the right hand side of Eq. (62) comes from small values of $|k_p|$ in the region $\mathcal{P}_\delta$. For $p_0 \in \mathcal{P}_\delta$ close to a stationary point $p_{0\alpha}$, k_p in Eq. (29) can be approximated by

$$k_p \approx \int_0^t dt' \left[\frac{\partial^2 V}{\partial r'^2} \left(\frac{\partial r'}{\partial p_0} \right)^2 + \frac{\partial V}{\partial r'} \frac{\partial^2 r'}{\partial p_0^2} \right] (p_0 - p_{0\alpha}). \quad (63)$$

Due to exponential divergence of neighboring trajectories in phase space, the main contribution to the right hand side of Eq. (63) comes from times $t' \approx t$. The time evolution of the quantity inside the bracket in Eq. (63) is given by the dynamics of the system described by H_0 . On average it increases as $[\delta x(t)/\delta x(0)]^2$, with $\delta x(t)$ being distance in phase space. With increasing time, the number of stationary points increases exponentially, roughly in the same way as $\delta x(t)/\delta x(0)$, since the oscillation of ΔS is mainly induced by local instability of trajectories.

Then, substituting Eq. (63) into Eq. (62), we have

$$\overline{M}(t) \propto \left[\frac{1}{D|\delta x(t)/\delta x(0)|} \right]. \quad (64)$$

When D changes slowly with p_0 and $\tilde{r}_0$, we have

$$\overline{M}(t) \propto I_\Lambda(t) \equiv e^{-\Lambda_1(t)t}, \quad \text{with} \quad \Lambda_1(t) = - \lim_{\delta x(0) \rightarrow 0} \frac{1}{t} \ln \left| \frac{\delta x(t)}{\delta x(0)} \right|^{-1}. \quad (65)$$

In systems with constant local Lyapunov exponents, Eq. (65) reduces to the usual Lyapunov decay with $\Lambda_1(t) = \lambda$. On the other hand, when fluctuation in local Lyapunov exponent cannot be neglected, $I_\Lambda(t)$ coincides with the $e^{-\lambda_1 t}$ decay in Ref. [20] in the limit $t \rightarrow \infty$, with $\lambda_1 = \lim_{t \rightarrow \infty} \Lambda_1(t)$.

B. Decay of the average of $\ln M(t)$

To understand the decaying behavior of the average of $\ln M(t)$ for initial Gaussian wave packets, we divide the time t into four time intervals, specifically, $(0, \tau_1)$, (τ_1, τ_2) , (τ_2, t_d) , and $[t_d, t_s)$. Here t_d is a time scale defined below, beyond which diagonal approximation can be used before average is performed, and t_s is the time at which the saturation value of fidelity is reached.

Within the first time interval, $M(t)$ is described by Eq. (35) for most of initial states. For σ not large, $\ln M(t)$ is close to zero. On the other hand, for quite large σ , the average of $\ln M(t)$ can be quite small (cf. Fig. 4).

For the second time interval (τ_1, τ_2) , Eq. (39) can be used to calculate $\ln M(t)$, for initial states with $\tilde{k}_p$ satisfying $|\sigma \tilde{k}_p| \gg \pi/w_p$. For this part of initial states, $|\tilde{k}_p|$ typically increases as $\delta x(t)/\delta x(0)$ [see Eq. (29)], as a result, the average of $\ln M(t)$ for this part of initial states

FIG. 13: Variation of $\Lambda(t)$ and $\Lambda_1(t)$ with t in the kicked rotator model at $K = 7$, with average performed over 10^6 random initial positions in phase space. The definitions of $\Lambda(t)$ and $\Lambda_1(t)$ are given in Eqs. (31) and (65), respectively. The value of $\Lambda(t)$ approaches the Lyapunov exponent $\lambda \approx 1.27$ quickly, as t increases.

behaves as $-2\Lambda(t)t$, where $\Lambda(t)$ is defined by Eq. (31). On the other hand, for initial states with small $|k_p|$, which lie in the neighborhoods of the stationary points of ΔS , fidelity decay is slower. Since the total size of the regions of p_0 with small $|k_p|$ is small compared with the domain of p_0 , the average of $\ln M(t)$ over all possible initial states has a decay rate between $\Lambda(t)$ and $2\Lambda(t)$. In a classical system with strong chaos, $\Lambda(t)$ approaches the Lyapunov exponent λ quickly, as seen in Fig. 13, therefore, in this time interval, the decay rate of the average of $\ln M(t)$ is usually close to, or a little larger than λ .

For t around τ_2 or longer, the main contribution to the average of $\ln M(t)$ is given by the neighborhood of stationary points and one can start from Eq. (60) in calculating $M(t)$. In the third time interval $[\tau_2, t_d)$, the number of stationary points within the effective window in p_0 is small, hence, diagonal approximation cannot be used in calculating the absolute value square of the right hand side of Eq. (60). We do not know much about the decay of the average of $\ln M(t)$ in this time interval. One should note that the third time interval is quite short, as a result of the exponential increment of the number of oscillations of ΔS .

In the fourth time interval $[t_d, t_s)$, diagonal approximation is applicable to the absolute value square of the right hand side of Eq. (60) before average is performed, due to the large number of stationary points within the

effective window in p_0 . Then, Eqs. (60) and (61) give

$$\begin{aligned} M(t) &\simeq \sum_{\alpha} |m_{\alpha}(t)|^2 \\ &= \sum_{\alpha} \frac{2\hbar \exp[-2(p_{0\alpha} - \tilde{p}_0)^2/w_p^2]}{w_p^2 |\Delta S''_{\alpha}|}. \end{aligned} \quad (66)$$

Using Eq. (29), we write $\Delta S''_{\alpha}$ as

$$\Delta S''_{\alpha} \approx \epsilon \int_0^t dt' \left[\frac{\partial^2 V}{\partial r'^2} \left(\frac{\partial r'}{\partial p_0} \right)^2 + \frac{\partial V}{\partial r'} \frac{\partial^2 r'}{\partial p_0^2} \right]. \quad (67)$$

Arguments similar to those leading from Eq. (63) to Eq. (64) show that, when the fluctuation of $|\delta x(t)/\delta x(0)|$ is small for p_0 within the effective window in the p_0 space, the main decaying behavior of a single fidelity is typically

$$M(t) \propto |\delta x(t)/\delta x(0)|^{-1}, \quad (68)$$

with $\delta x(0)$ being a small displacement from $(\tilde{r}_0, \tilde{p}_0)$, the center of the initial Gaussian packet. Then, it is ready to obtain

$$\exp[\overline{\ln M(t)}] \propto e^{-\Lambda(t)t} \simeq e^{-\lambda t}. \quad (69)$$

where the second equation is obtained, since $\Lambda(t)$ is usually close to the Lyapunov exponent λ within this time interval.

Since the fluctuation of $|\delta x(t)/\delta x(0)|$ within the effective window in p_0 increases with time, Eq. (69) becomes invalid for t long enough. In the long time limit, the fluctuation of $|\delta x(t)/\delta x(0)|$ within the effective window in p_0 has similar properties as in the whole p_0 domain, then, the average of $\ln M(t)$ has the $\Lambda_1(t)$ decay in Eq. (65), with $\Lambda_1(t)$ taking the value λ_1 . For intermediate times, it is reasonable to expect that the decaying rate of the average of $\ln M(t)$ decreases from the Lyapunov exponent and approaches $\Lambda_1(t)$ with increasing t .

Combining the above results, it is seen that there indeed exists a certain short time interval, in which the average of $\ln M(t)$ follows roughly the Lyapunov decay, as observed in the kicked top model [19]. Specifically, the decaying rate of the average of $\ln M(t)$ is close to or a little larger than the Lyapunov exponent in the second time interval; then, beyond the short third time interval, it decreases from the Lyapunov exponent and approaches $\Lambda_1(t)$ at long time.

We have tested these predictions, as well as those in the previous section, in the kicked rotator model at $K = 7$, which are shown in Fig. 14. It is seen in the figure that the average of $\ln M(t)$ decays a little faster than the $\Lambda(t)$ decay (as well as the Lyapunov decay) initially, then, after a transient time, it decays a little slower than the Lyapunov decay, but obviously faster than the $\Lambda_1(t)$ decay. The predicted long time $\Lambda_1(t)$ decay for the average of $\ln M(t)$ is not seen at $K = 7$, because K is not large enough for the value of N taken. We mention that the λ_1

FIG. 14: Fidelity decay in the kicked rotator model at $K = 7$, $N = 2^{17}$, $\sigma = 20$. Average is performed over 500 initial Gaussian wave packets with $\xi = \sqrt{\hbar}$, whose centers are chosen randomly in the chaotic sea in phase space. The $\Lambda(t)$ and $\Lambda_1(t)$ decays are the predictions in Eqs. (69) and (65), respectively, with the values of $\Lambda(t)$ and $\Lambda_1(t)$ shown in Fig. 13. Decay of the average of $M(t)$ is described by the $\Lambda_1(t)$ decay. The average of $\ln M(t)$ is a little faster than the $\Lambda(t)$ decay in an initial short time interval, as predicted by the theory.

decay at long time has indeed been observed for $K = 10$ in Ref. [20].

Finally, for quite large σ , the initial approximate Lyapunov decay discussed above may disappear. Indeed, in this case, $|\ln M(t)|$ can be quite large for $t < \tau_1$, as seen in Eq. (35). The average of $\ln M(t)$ for short time t is in fact dominated by contributions described by Eq. (35), even beyond $\bar{\tau}_1$, since the value of τ_1 fluctuates with respect to the initial condition, i.e., for some initial states τ_1 can be relatively long. Hence, the average of $\ln M(t)$ can be obviously smaller than the prediction of the Lyapunov decay in the second time interval, as shown numerically in [20].

VII. CONCLUSIONS AND DISCUSSIONS

In this paper, we have improved the uniform semiclassical approximation to fidelity by considering the second order term in the Taylor expansion of action, which is important for fidelity of initial Gaussian wave packets with width of the order $\sqrt{\hbar}$. Short-time-decay of fidelity is analyzed, which is initial-state-dependent, in particular, two time scales have been introduced and studied in detail for initial Gaussian wave packets. Initial FGR decay of fidelity in the perturbative regime is confirmed by direct numerical calculations. Non-FGR decay in the FGR regime in systems with weak chaos in the classical limit is explained by relating the distribution of action difference to the Levy distribution. The average of the logarithm

FIG. 15: Schematic diagram for fidelity decay of initial point sources in systems with constant local Lyapunov exponents in the classical limit. t_B is the breakdown time of semiclassical approximation, and t_H is the Heisenberg time, beyond which the Gaussian decay sets in. σ_d and σ_r are two perturbation scales introduced in Ref. [28]. Below σ_d , one has the FGR decay for $t < t_B$, and above σ_r is the Lyapunov regime, in which the Lyapunov decay appears beyond the first kick.

of fidelity is shown to have an approximate Lyapunov decay within some time intervals, in the Lyapunov regime in systems possessing large fluctuations of the finite-time Lyapunov exponents in the classical limit.

As we have demonstrated that fidelity has a decaying behavior richer than the simple picture mentioned in the beginning of the introduction with just four distinct regimes. In Fig. 15, we present a schematic diagram for the present understanding of fidelity decay of initial point sources in systems possessing constant local Lyapunov exponent in the classical limit. For initial Gaussian wave packets, short time decay is more complex than for initial point sources, for which two time scales τ_1 and τ_2 should be introduced, as discussed in this paper. When the underlying classical dynamics has large fluctuation in the finite-time Lyapunov exponent, the decaying rate of fidelity in the Lyapunov regime is not given by the Lyapunov exponent.

APPENDIX A: DEPENDENCE OF FIDELITY DECAY ON PERTURBATION STRENGTH IN DEEP LYAPUNOV REGIME FOR INITIAL POINT SOURCES

In this appendix, we consider the dependence of fidelity decay on perturbation strength in the deep Lyapunov regime for initial point sources, which can be estimated by using Eq. (21). Let us first divide the domain $[0, 2\pi)$ of p_0 into a series of subregions, $[p_{0j}, p_{0(j+1)})$, so that within each of the subregions the phase $\Delta S/\hbar$ of the integrand on the right hand side of Eq. (21) can be approximated by a linear function,

$$\Delta S/\hbar \simeq \sigma(k_j p_0 + b_j), \quad \text{for } p_0 \in [p_{0j}, p_{0(j+1)}), \quad (\text{A1})$$

where the parameters k_j and b_j do not depend on p_0 . Here $p_{0j} = 0$ for $j = 1$ and $p_{0j} = 2\pi$ for $j = N_X + 1$, with N_X denoting the number of the subregions. Substituting Eq. (A1) into Eq. (21), we have

$$m_p(t) \simeq \frac{1}{2\pi i \sigma} \sum_{j=1}^{N_X} X_j \quad \text{with} \quad X_j := \frac{1}{k_j} (e^{i\sigma k_j p_{0(j+1)}} - e^{i\sigma k_j p_{0j}}) e^{i\sigma b_j}. \quad (\text{A2})$$

In arranging the subregions, we require that N_X should be as small as possible, conditional on that the linear approximation in Eq. (A1) does not lose the main contribution to the right hand side of Eq. (21). Since the phase $\Delta S/\hbar$ is proportional σ , N_X increases approximately linearly with σ . In the deep Lyapunov regime with quite large σ , for the subregions chosen in this way, the phase of X_j , which is approximately proportional to σ , can be regarded as random with respect to j and r_0 , then, diagonal approximation can be used in computing the averaged fidelity,

$$\overline{M}_p(t) = \frac{1}{2\pi} \int dr_0 |m_p(t)|^2 \simeq \frac{1}{(2\pi\sigma)^2} \sum_{j=1}^{N_X} |X_j|^2, \quad (\text{A3})$$

where we assume that fluctuation of N_X with respect to r_0 is small. Finally, using $N_X \propto \sigma$, we have the following approximation,

$$\overline{M}_p(t) \propto 1/\sigma, \quad \text{for } \sigma \gg 1. \quad (\text{A4})$$
